Follow-up: who self-cures, and who is harmed by unnecessary contact?

Hi all,

I may be joining dots that do not belong together, so please challenge the premise.

Collections wants a prioritisation model, but validation must separate default risk from the effect of different contact strategies. There is no confirmed problem yet; this is a request to test an assumption before it becomes policy.

Could the answer be that some customers self-cure without intervention? Or are we actually seeing that contact channel changes promise-kept rates? I also do not want us to miss the possibility that high-risk customers need tailored arrangements rather than more attempts.

This has returned because the previous answer was useful but not strong enough to become a standing rule. Use November 2025 as the new evidence point rather than recycling the earlier conclusion. The practical decision is whether a model can support treatment allocation and what experiment is needed next. Please send a working Excel file with the exception population and clear columns; I need the exceptions and counter-examples, not only an average.

Work from collections cases, promises to pay and recovery payments; customer contacts, complaints and suggestions; transaction-level timestamps, channels, amounts, statuses and error context; the latest closed loan files available by the request date, including affordability, pricing and origination risk fields. Observational data cannot prove treatment causality; recommend a controlled test where appropriate.

Regards
