Reduce false positives without weakening controls

Hi all,

I may be joining dots that do not belong together, so please challenge the premise.

Investigators report that some suspicious patterns disappear once transaction timing, retries and customer contacts are reconstructed. Please start with the decision we need to make, then show whether the available evidence is strong enough to support it.

Could the answer be that repeated attempts inflate velocity? Or are we actually seeing that bank-side delay creates impossible sequences? I also do not want us to miss the possibility that a known service interaction explains the change.

We looked at a version of this before. For the November 2019 review, please show what changed and whether the earlier conclusion still holds. The practical decision is which alert features should be corrected, retained or routed elsewhere. Please send a Power BI page with drill-through to a reproducible case list; I need the exceptions and counter-examples, not only an average.

Work from transaction-level timestamps, channels, amounts, statuses and error context; ATM attempts, host responses, PIN attempts, blocked-card state and latency; customer contacts, complaints and suggestions; monthly account snapshots, status events, limits, product enrolments and signatories. A plausible explanation is not automatic clearance; investigators still own the decision.

Regards
