The retry pattern needs to be separated from demand

Morning,

I need help with something that sounds simple but probably is not.

During service degradation, repeated attempts can inflate volume and obscure the number of customers actually affected. The discussion is currently being driven by anecdotes, and the teams involved are describing the same customers differently.

The questions I would ask in the room are:

1. What would we expect to see if customers retry the same action within minutes?
2. What evidence would instead support that channel switching follows a timeout?
3. How do we rule out that automatic retry and human retry are being mixed?

This has returned because the previous answer was useful but not strong enough to become a standing rule. Use July 2020 as the new evidence point rather than recycling the earlier conclusion. Please work towards how monitoring should count affected customers and when retry controls should activate. A useful output would be a control view with the exceptions, owner and reason each item was included.

Use transaction-level timestamps, channels, amounts, statuses and error context; ATM attempts, host responses, PIN attempts, blocked-card state and latency. One caution: Without application session IDs, use account, amount, channel and time proximity as an explicit matching heuristic.

Regards
